# CULTURE OF ALGAE ON DOMESTIC SEWAGE UNDER NATURAL CLIMATIC CONDITIONS 

#### Abstract

Algae were cultured for 1 year on domestic sewage. It was proved that their effective cultures could be conducted in spring, summer, and autumn which was supported by distinct increment of algal dry weight and protein content. Increment in COD values evidenced an effective utilization of some components of domestic sewage, and thus its purification.

## 1. INTRODUCTION

Intense culture of algae evokes a wide interest due to high possibilities of their biomass utilization in various branches of economy.

Algae contain many valuable components, so they may be used as a fertilizer improving the structure of soil by increasing the content of humus compounds [7]. In fish farming algae may be used either directly as fodder for plant-feeding fish or indirectly as feed for protozoa serving as food for fish [7]. They have also found application as fodder [10] or premixes [7] for other animals [8] because of high contents of nutritive substances [8], vitamins (B,C,D, $\mathrm{E}, \mathrm{K}$ ), and microelements (B, Co, Cr, J, Mo, Ni, Zn ) [7]. In some countries, e.g., in Japan, China, Corea, New Zealand, Polynesia, Australia, South America, and Nigeria, some species of algae are used as food products [3].

Culture of algae on some kinds of wastewater [11] is of interest because of its role in utilization of waste substances and treatment of wastewater, as well as in neutralization of eutrophication of receivers. Our investigations performed under laboratory conditions have confirmed such a possibility [6].

Cultures of algae under natural climatic conditions were initiated in different countries in the fifties, e.g., algal farms in Trebon (Czechoslovakia) [1], Dortmund (West Germany), and Tokio [9]. Algae in pilot-scale cultures belong to the genera Scenedesmus acutus, Chlorella vulgaris, and Spirulina maxima [1].

[^0]The present work is an attempt to conduct algal cultures on domestic sewage in different seasons of the year under natural atmospheric conditions.

## 2. MATERIAL AND METHODS

The strain Chlorella sp. 394 used for the culture was selected by us from 21 strains because of its high protein content and fast development [6] which guarantee the possibility of obtaining substantial amounts of biomass in short time. The experiments were conducted for 30 days under continuous culture conditions. $0.75 \mathrm{dm}^{3}$ of domestic sewage filtrated per 24 h through a filter paper was proportioned to $2 \mathrm{dm}^{3}$ culture chambers. Domestic sewage was taken from the intermediate pumping station "Szczytniki" in Wrocław. The culture was conducted under natural climatic conditions, in winter, spring, summer, and autumn. At the same time the control culture was conducted on the Uspienski medium [4].

The development of algae was estimated on the basis of dry weight and the number of cells determined in the Fuchs-Rosenthal chamber and calculated for $1 \mathrm{~cm}^{3}$ of the culture. In the obtained biomass, the total protein content was determined by the Larry method [5].

Chemical oxygen demand of domestic sewage flowing into the culture chamber and in the effluent was determined by dichromate method and used to estimate the efficiency of treatment [2].

## 3. RESULTS OF INVESTIGATIONS

Culture of algae on domestic sewage was conducted in four seasons of the year. Selected climatic and metheorological parameters dominating in the separate periods of investigations are given in tab. 1 .

Spring series of investigations was conducted from late April to early May. In this period, minimal temperature amounted to $272.9 \mathrm{~K}\left(-0.1^{\circ} \mathrm{C}\right)$ and the maximal one equalled 279.2 K $\left(+24.2^{\circ} \mathrm{C}\right)$, while the mean daily temperature ranged from $276.5 \mathrm{~K}\left(+3.5^{\circ} \mathrm{C}\right)$ to 288.8 K $\left(+15.8^{\circ} \mathrm{C}\right)$. The length of day varied from 13 h 22 min . to 15 h 22 min .

During 720 h of spring investigations, 4 days were totally sunless and the sum of sunny hours amounted to 136 h 30 min . Results obtained for this series are presented in tabs. 2 and 3. The data indicate a constant increment in the number of algal cells. The development of algae on domestic sewage was more intensive than that on the Uspienski medium. In the last day of the experiment, the number of algal cells in experimental chambers was $124 \%$ with respect to that in the control chamber.

In both experimental and control cultures, the dry weight increased with time, being however higher in experimental reactors. In the last day of investigations, dry weight of algae grown on domestic sewage amounted to $139.4 \%$ with respect to that in the control culture. Total protein content in algae grown on domestic sewage, determined in 30th day of investigations, was $302.4 \%$ of that found in the control culture. The values of COD given in tab. 3 indicate a high variation in chemical composition of domestic sewage used as culture medium. That is why, each time the COD reduction (in percent) of a treated sewage was calculated with respect to the sewage being proportioned. For the particular series, these values are also presented in tab. 3 .

Climatic and meteorological data for spring, summer, autum, and winter series of experiments

| Season of year | Length of day h | Number of sunless days | Insolation h/day | Total number of sunny hours in series h | Sunny hours \% | Range |  |  |

|  | 3 | 244.0 | 115.0 | 129.0 | 52.9 |
|  | 8 | 209.0 | 107.9 | 101.0 | 48.3 |
|  | 11 | 209.0 | 106.9 | 102.1 | 54.5 |
|  | 15 | 217.8 | 91.3 | 126.5 | 58.1 |
|  | 18 | 217.8 | 91.0 | 126.8 | 58.2 |
|  | 22 | 276.4 | 82.0 | 194.4 | 70.9 |
|  | 25 | 276.4 | 100.0 | 176.4 | 63.8 |
|  | 30 | 208.2 | 82.6 | 125.6 | 60.5 |

In spring, the COD values of the proportioned domestic sewage ranged from 233.8 to 446 $\mathrm{mg} \mathrm{O}_{2} / \mathrm{dm}^{3}$. By comparing the COD values of the proportioned and treated domestic sewage, it could be stated that large amounts of the sewage components have been utilized by algae. The COD reduction in the last day of experiment was as high as $92.55 \%$.

The second (summer) series of experiments lasted from mid June to mid July. The highest temperatures recorded in this series ranged from $283.3 \mathrm{~K}\left(+10.3^{\circ} \mathrm{C}\right)$ to $303.6 \mathrm{~K}\left(+30.6^{\circ} \mathrm{C}\right)$, whereas mean daily temperatures varied from $285.4 \mathrm{~K}\left(+12.4^{\circ} \mathrm{C}\right)$ to $296.5 \mathrm{~K}\left(+23.5^{\circ} \mathrm{C}\right)$, and the lowest daily temperatures ranged between $281.1 \mathrm{~K}\left(+8.1^{\circ} \mathrm{C}\right)$ and $288.9 \mathrm{~K}\left(+15.9^{\circ} \mathrm{C}\right)$. The sum of sunny hours during 720 h investigations amounted to 171 h 57 min . In this series, the increment of algae grown on domestic sewage was much higher than that in control culture.

The number of algal cells determined in experimental reactors was higher than that in control chambers. In the last day of investigations, the number of cells in experimental chamber amounted to $121.2 \%$ with respect to that determined in control chamber. Like in spring series, the increments in dry weight and total protein of algae grown in experimental cultures were much higher. In 30th day of investigations, dry weight and total protein of algae in experimental reactors determined with respect to those in control culture amounted to $161.4 \%$ and $243 \%$, respectively.

The COD values of proportioned and treated sewage were also subject to high variations, ranging from 216 to $384 \mathrm{mg} \mathrm{O}_{2} / \mathrm{dm}^{3}$ for the former, and from 52.5 to $205.4 \mathrm{mg} \mathrm{O}_{2} / \mathrm{dm}^{3}$ for the latter. COD reduction varied from $46.5 \%$ to $78.2 \%$.

Autumn series of experiments was conducted from October to November. During this period mean daily temperatures ranged from $277.0 \mathrm{~K}\left(+4^{\circ} \mathrm{C}\right)$ to $290.9 \mathrm{~K}\left(+17.9^{\circ} \mathrm{C}\right)$. The lowest daily temperature amounted to $273.5 \mathrm{~K}\left(+0.5^{\circ} \mathrm{C}\right)$, while the highest one was equal to $298.2 \mathrm{~K}\left(+25.2^{\circ} \mathrm{C}\right)$. In this series, the sum of sunny hours was 105 h 6 min ., 8 days were totally sunless.

In this series of investigations, the numbers of algal cells both in experimental and control cultures decreased with respect to $14.2 \cdot 10^{6}$ cells $/ \mathrm{cm}^{3}$ at the beginning of this experiment. In the course of the investigations, the minimal number of cells in experimental and control chambers amounted to about $11.5 \cdot 10^{6} / \mathrm{cm}^{3}$ and about $10^{6} / \mathrm{cm}^{3}$, respectively, thus the rate of cell divisions significantly decreased. In the last day of experiment, the number of cells in experimental reactors determined with respect to control samples was the lowest one being scarcely $102.7 \%$.

Dry weights of algae grown in experimental and control chambers increased with time. In the 30th day of experiment, dry weight of algae in experimental chambers, determined with respect to that in control samples, amounted to $135.5 \%$. The same trend was observed while determining the total protein, which in algae grown on domestic sewage, determined with respect to that in control reactor, was equal to $253.9 \%$.

The COD values of proportioned sewage ranged from 208.2 to $276.4 \mathrm{mg} \mathrm{O}_{2} / \mathrm{dm}^{3}$. Culture of algae on domestic sewage led to the reduction of pollutants, manifested by the reduction of COD value. COD values of treated sewage varied within 82.0 and $124.4 \mathrm{mg} \mathrm{O}_{2} / \mathrm{dm}^{3}$. In this series of experiments, COD reduction ranged from $48.3 \%$ to $70.9 \%$.

Low temperatures recorded in winter made our investigations impossible. Minimum daily temperature ranged from $254.9 \mathrm{~K}\left(-18.1^{\circ} \mathrm{C}\right)$ to $270.1 \mathrm{~K}\left(-2.9^{\circ} \mathrm{C}\right)$, and mean daily temperature varied within $264 \mathrm{~K}\left(-9^{\circ} \mathrm{C}\right)$ and $271.8 \mathrm{~K}\left(-1.2^{\circ} \mathrm{C}\right)$.

## 4. DISCUSSION OF RESULTS

The obtained results show that the cultures of algae can be conducted in spring, summer, and autumn.

The development of algae in these seasons of the year was determined basing on the cell number, dry weight, and total protein content. While comparing the obtained data, it has been stated that the intensity of algal growth in domestic sewage was much higher than that in control culture. This proves that the sewage being investigated contains some components advantageous for the development of algal population.

In spring and summer series, the increments in biomass and total protein of algae were accompanied with the increment in cell numbers. Only in autumn the stated drop of the cell number with respect to the inoculum was associated with distinct increments in dry weight and total protein. This phenomenon was stated both in experimental and control chambers. Dry weight in experimental and control chambers ranged from 0.23 to $2.14 \mathrm{mg} / \mathrm{dm}^{3}$ and from 0.23 to $1.58 \mathrm{mg} / \mathrm{dm}^{3}$, respectively, whereas total protein, equal initially to $46.4 \mathrm{mg} / \mathrm{dm}^{3}$, increased in these chambers to $542 \mathrm{mg} / \mathrm{dm}^{3}$ and $252.8 \mathrm{mg} / \mathrm{dm}^{3}$, respectively.

It seems possible that the decrease in the number of algal cells observed in autumn was related to a greater number of sunless days ( 8 sunless days recorded in this time). This hypothesis is supported by the fact that in spring the numbers of algal cells increased distinctly (from $13.528 \cdot 10^{6}$ to $21.190 \cdot 10^{6} / \mathrm{cm}^{3}$ ) though thermal conditions were similar to those in autumn, but the number of sunless days was two times smaller ( 4 sunless days). Thus, climatic conditions and varying composition of sewage could result in the decreasing rate of cell divisions with a simultaneous increment in biomass.

Hence, the sizes of newly formed cells had to be larger and this fact was confirmed by microscopic observations.

Increments in biomass and total protein content associated with a reduced value of COD prove that some sewage components are utilized by algae. In all investigation periods, $C O D$ values of the proportioned domestic sewage used as culture medium varied, giving the evidence to the variable chemical composition of this sewage. The highest COD removal was stated in spring and amounted to $4.6 \%-92.5 \%$. In summer, it varied from $46.5 \%$ to $78.2 \%$, and in autumn, from $48.3 \%$ to $70.9 \%$.

The obtained results indicate that in autumn the amount of high-protein biomass obtained in experimental reactor was the highest, the effects of sewage treatment being somewhat worse, in particular, if compared with those obtained in spring.

Summing up, it should be stated that algal culture on domestic sewage (used as a culture medium) can be conducted in natural climatic conditions. Such a culture may be conducted during the whole year, if the culture chambers are placed in rcoms illuminated periodically.

## HODOWLA GLONÓW NA ŚCIEKACH KOMUNALNYCH W NATURALNYCH WARUNKACH KLIMATYCZNYCH

W ście kach bytowo-gospodarczy ch hodowano glony przez okres 1 roku. Wy kazano, iż możliwe jest prowadzenie wydajnej hodowli przez znaczną czẹ́ść roku, o czym świadczy przyrost suchej masy i białka glonowego. Obniżenie chemicznego zapotrzebowania tlenu wskazuje, iż glony efektywnie obniżają stopień zanieczy szczenia ścieków by towo-gospodarczy ch.

## РАЗВЕДЕНИЕ ВОДОРОСЛЕЙ НА КОММУНАЛЬНЬХ СТОЧНЫХ ВОДАХ В НАТУРАЛЬНЫХ КЛИМАТИЧЕСКИХ УСЛОВИЯХ

В быгово-хозяйстенных сточных водах разводили водоросли в течение 1 года. Обнаружили, что возможно ведение эффективного разведения в течение значительной части года, о чем свидетельствует привес сухой массы и белков. Понижение ХПК показывает, что водоросли эффективно понижают степень загрязнения бытово-хозяйственных сточных вод.
